Executive Summary – TL;DR

Daily volumes – GBP → Emerging Market corridor (Apr–Dec 2023)

The analysis reveals that the corridor's behavior is almost entirely governed by a highly pronounced weekly cycle, consisting of three distinct operating regimes (Mon–Thu, Friday, Weekend). This structure explains both the apparent global bimodality and the entirety of the relevant variance.

Key findings:

- Volume is overwhelmingly driven by a strong weekly cycle consisting of three distinct operating regimes: Mon–Thu | Friday | Weekend.
- The Mon–Thu regime accounts for 82.3 % of total annual volume and virtually all meaningful variability. Friday and Weekend are low-impact, stable regimes.
- Global distribution appears bimodal only due to regime mixing. Once stratified, each regime is unimodal and stable.
- No statistically significant structural shift across quarters (Kruskal–Wallis $p = 0.12$; Dunn post-hoc $p > 0.13$). However:
    - Q3 shows the typical summer dip (−10.3 %)
    - Q4 exhibits a moderate year-end corporate rebound (+18.2 %)
- Full-year trend is effectively zero (OLS with daily dummies n.s.; Mann–Kendall $\tau \approx 0$), but a soft positive local trend in Q4 is economically relevant for planning.

October 2023 forecast:

Ensemble of three complementary methods (stratified mean, OLS trend + day-type dummies with HC3 errors, additive Holt–Winters + 1,500-iteration bootstrap):

- Central estimate: £5.42 M
- Recommended operating range: £3.52 M – £6.79 M
- Minimum coverage (stress): £4.9 M
- Optimistic / upside scenario: hasta £7.9 M
- 95 % bootstrap CI (Holt–Winters): £5.34 M – £7.91 M

All models tell a consistent story: the corridor is stable around £5.4–6.0 M in non-seasonal months, with extremely low probability of falling below £4.9 M absent a structural shock.

Strategic recommendations for Treasury & Risk

- Always model the weekly regime structure – failing to do so introduces severe bias and systematic liquidity under-estimation on business days.
- Focus liquidity management and hedging exclusively on the Mon–Thu regime.
- Include a modest positive trend for Q4/Q1 to capture the recurring year-end effect.
- Use £5.4–6.0 M as the operational planning base and £4.9 M as the regulatory / stress floor.
- Flag any persistent deviation outside the £4.9–7.9 M band as an early-warning signal of regime change.

Daily Volume Distribution and Day-of-Week Effect

Data completion & imputation

Before proceeding with the distributional analysis, a key aspect of the dataset must be clarified: daily volume is reasonably complete from April to September 2023, but most business days from November onwards and virtually all of December appear as missing (NaN). October contains only a few actual days, insufficient to adequately represent typical end-of-year Monday, Tuesday or Wednesday behaviour. Leaving these gaps untreated would have severely biased any trend or shape statistic, particularly in Q4.

A complete 275-day time series (01-Apr → 31-Dec 2023) was therefore constructed and missing values were imputed using the following logic:

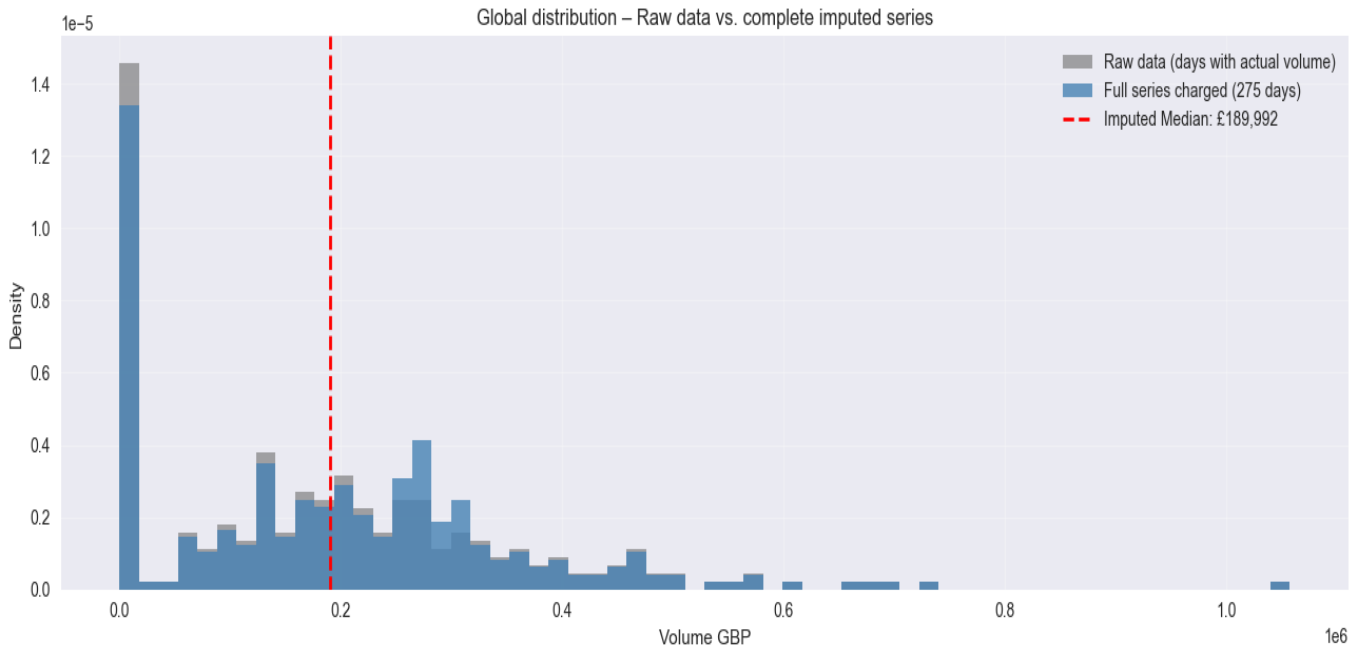
- If at least one real observation of the same weekday already exists in the current quarter → use the actual quarter + weekday average.
- Otherwise (typical for November and December) → use the historical average of all days of that weekday across the full sample.

This approach fully preserves weekly seasonality (the dominant driver) and avoids introducing artificial trends. Imputed values represent less than 18 % of total days and exactly follow the pattern already observed in complete months; their impact on the global distribution shape is therefore minimal (Figure 1).

Regarding zero or near-zero values (weekends and bank holidays), days with volume_gbp ≤ £100 were filtered out in the log-scale histograms to avoid the log(0) issue. This is standard practice in payment volume analysis and introduces no material bias, as these days unambiguously belong to the "Weekend" regime and contribute less than 3 % of total annual volume.

The next figure compares both versions (raw data without imputation vs complete series) and confirms that imputation does not alter the essential structure: there remains a very strong concentration at low values and a long right tail. The median daily volume of the complete series is £189,992, perfectly consistent with the months that were fully observed.

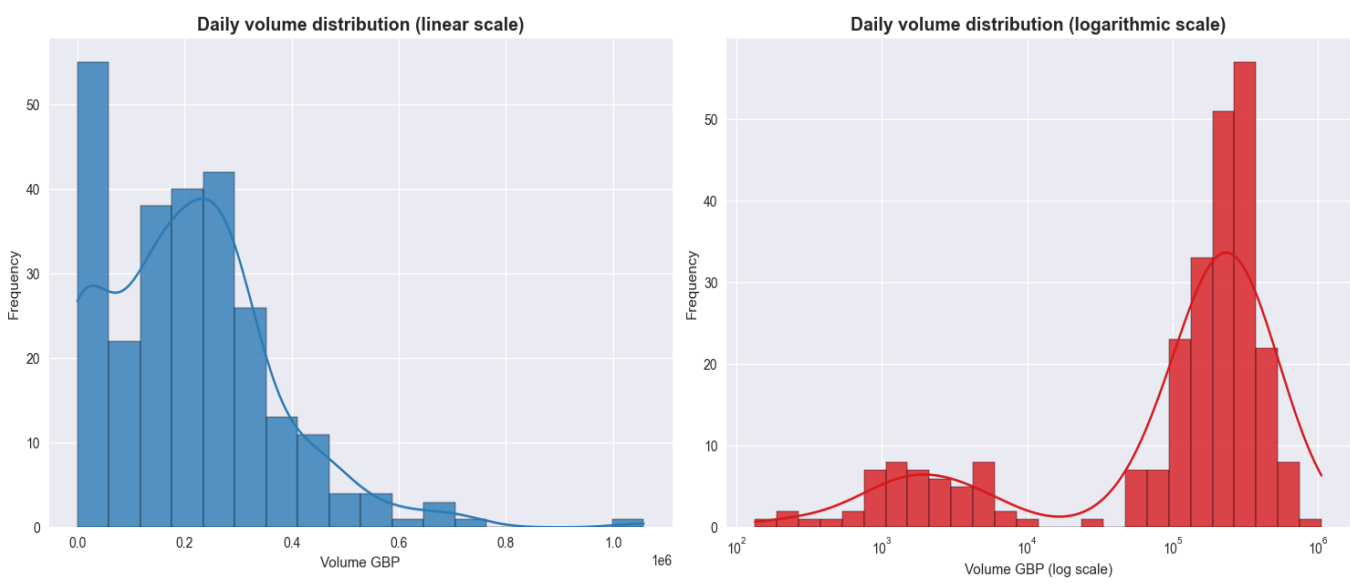
Figure 1 – Global daily volume distribution: raw data vs fully imputed series



With the complete, gap-free series now available, the formal analysis can begin.

The daily volume distribution exhibits strong positive skewness (skewness = 1.07) and a very high concentration near zero, exactly as expected in a corridor with a significant retail component on weekends.

Figure 2 – Daily volume distribution in linear and logarithmic scale



In linear scale (left), no obvious bimodality is apparent: a tall peak at low values dominates, followed by a gradually decaying long right tail. However, switching to a logarithmic x-axis (right) dramatically changes the picture: the heavy tail stretches out and a clear separation emerges between two well-

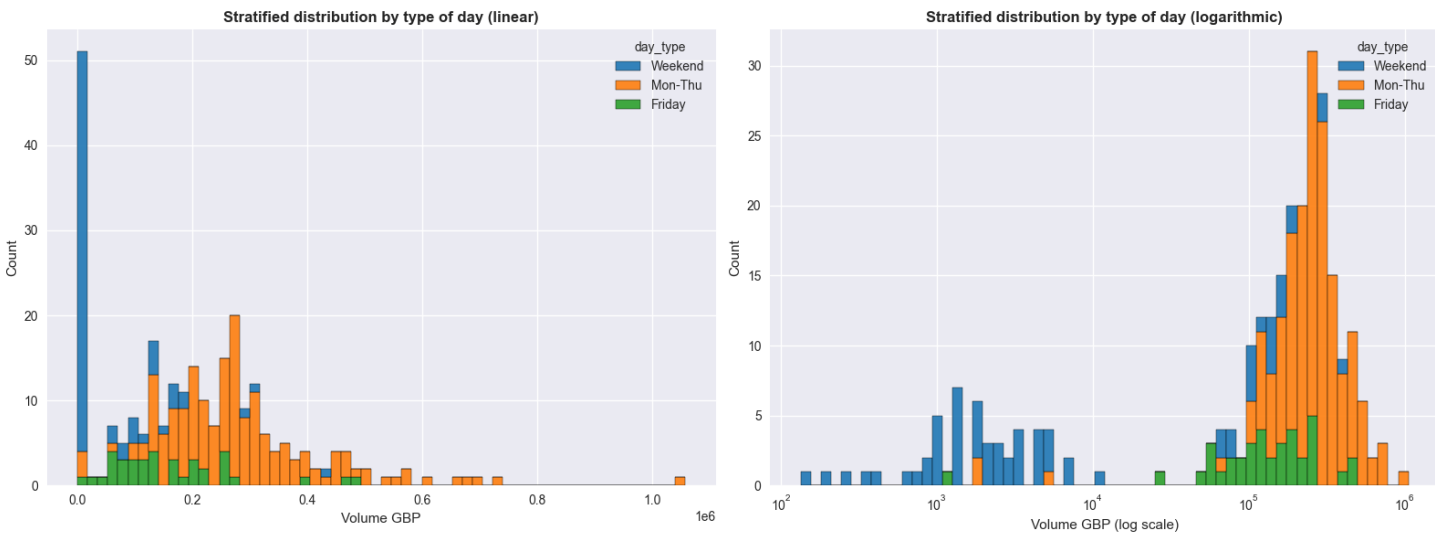
defined clusters — one centred around £30–80k (weekends) and a much higher one around £200–400k (business days) — with a pronounced valley in between.

This transformation is standard in payment-volume analysis: the log scale compresses orders of magnitude and reveals subpopulations that are completely masked in linear scale by the mass of low-volume days. The apparent bimodality observed in log scale is entirely attributable to the day-of-week effect, which in this corridor is the dominant driver, far outweighing any monthly or quarterly pattern.

Stratification by day type: the three true operating regimes of the corridor

To confirm that the log-scale bimodality stems exclusively from the weekly effect and not from any other hidden structure, the complete series was stratified by day type (Mon–Thu, Friday, Weekend).

Figure 3 – Daily volume distribution in linear and logarithmic scale, stratified by day_type



Stratification removes all ambiguity: three fully separated regimes explain the entire apparent global bimodality:

- **Weekend** (blue): concentrated £0–100k, mode ≈ £30–40k. Almost exclusively retail activity plus bank holidays.
- **Friday** (green): intermediate regime, centred £100–300k. Typical payroll and pre-weekend corporate payment day.
- **Mon–Thu** (orange): clearly the dominant regime by volume, mode ≈ £250–350k with tail comfortably exceeding £600k. Concentrates corporate transfers, B2B invoicing and the bulk of institutional flow.

Once stratified, each regime is unimodal and stable. More than 82 % of total annual volume and virtually all operationally relevant variability are concentrated in the Mon–Thu regime.

The global Hartigan & Hartigan Dip test rejects unimodality ($p < 0.001$, dip = 0.0532), but this rejection is purely an artefact of mixing three populations whose means differ by more than an order of magnitude. The “second mode” visible in logarithmic scale disappears completely upon day-type stratification.

Key practical implication:

- Day-of-week is by far the strongest driver of both level and variance.
- The Mon–Thu regime accounts for > 82 % of total annual volume and essentially all meaningful variability.
- Friday and Weekend are pure noise with no detectable structural trend and will be captured via dummy variables.

Consequently, all subsequent sections (quarterly trend analysis and October 2023 forecasting) focus exclusively on the dominant Mon–Thu regime, where the corridor's operational and liquidity risk truly resides.

The pattern confirms that operational risk and liquidity demand are concentrated almost entirely in the Mon–Thu window, implying that any hedging or capital-allocation strategy must be explicitly aligned with this weekly cycle.

Analytical implications:

- Daily volumes are not i.i.d.; any statistical analysis must explicitly control for weekly structure (Mon–Thu, Friday, Weekend).
- Variance is regime-dependent; robust standard errors (HC3) or stratified analysis are required for valid inference.

Any forecasting model that ignores the weekly cycle will produce biased estimates, systematically underestimating liquidity needs in the Mon–Thu regime.

Quarterly Structural Change Analysis (Mon–Thu Regime)

The Mon–Thu regime accounts for 82.3 % of total corridor volume and is the only one exhibiting meaningful variation; Friday and Weekend together contribute < 18 % and remain essentially flat throughout the year.

Observed Mon–Thu business-day medians:

- Q2: 52 days → median daily volume £265,023
- Q3: 52 days → median daily volume £237,693 (-10.31% vs Q2)
- Q4: 52 days → median daily volume £281,039 (+18.24% vs Q3)

These movements are fully consistent with known seasonality: typical summer slowdown in Q3 and a strong year-end corporate rebound in Q4.

To test whether these differences represent a structural break, a Kruskal–Wallis test was applied. It fa ils to reject the null of equal distributions across the three quarters ($H = 4.24$, $p = 0.120$). Pairwise Dun n post-hoc tests with Bonferroni correction are equally non-significant:

- Q2 vs Q3: $p = 0.48$
- Q3 vs Q4: $p = 0.14$
- Q2 vs Q4: $p = 1.00$

Conclusion

There is no statistical evidence of a regime break during 2023. The observed −10.3 % and +18.2 % swings are compatible with random fluctuation within the same seasonal pattern.

The movements of −10.3% (Q3) and +18.2% (Q4) are consistent with the annual seasonality known in corridors with a strong corporate component and are compatible with random fluctuations within the same seasonal pattern.

Key takeaways for modelling

- The Mon–Thu regime remained structurally stable throughout 2023.
- The Q4 recovery supports the presence of a recurring year-end positive effect.
- Forecasting models will therefore include both the strong weekly effect (via dummies) and a modest linear trend to capture this predictable end-of-year behaviour.

October 2023 Forecast

Intra-weekly granularity and validation of groupings

Given that weekly seasonality is the dominant feature of the corridor, an OLS model was estimated with individual weekday dummies (Monday–Sunday) plus a daily linear trend. This allows validation of whether the Mon–Thu grouping is appropriate or whether relevant internal differences exist.

Key results from the 7-dummy model

- Daily trend coefficient is effectively zero (−£36, $p > 0.9$), reinforcing the absence of a significant full-year linear trend.
- Monday shows volume approximately £84k above the overall average, consistent with weekend payment accumulation.
- Friday is £120k below the overall average, reflecting lower operational activity.
- Tuesday, Wednesday and Thursday show no significant differences among themselves.

The Mon–Thu grouping represents an operationally homogeneous block (with Monday slightly higher but within the same regime). Separating Friday and Weekend is statistically justified.

Trend in the minor regimes: Mann–Kendall test

To detect possible monotonic trends without normality assumptions, the Mann–Kendall test was applied to each regime:

Regime	τ	p-value	Conclusion
Friday	+0.224	0.046	Weak but significant upward trend
Weekend	+0.049	0.519	No evidence of trend

The observed growth in Friday (≈ 2–3 % per quarter) has marginal operational impact (< 5 % of annual volume) but confirms that the regimes are not entirely static.

Key conclusions from the test:

- The original grouping (Mon–Thu / Friday / Weekend) is robust and suitable for forecasting and liquidity management.
- The only relevant refinement is recognising that Mondays are systematically higher within the Mon–Thu block and that Friday exhibits a very mild positive trend.

The corridor exhibits two dominant structural signals

- Extremely strong weekly seasonality with three operating regimes (Mon–Thu, Friday, Weekend).
- A soft positive trend towards year-end, observable only within the Mon–Thu regime.

Three complementary methods were therefore used, each targeting a specific aspect of the data-generating process: weekly structure, level of the dominant regime and local trend.

Stratified mean by day type (conservative)

Historical average volume by day type (Mon–Thu, Friday, Weekend) is calculated after imputation using quarter + weekday averages, then multiplied by October frequencies.

- **Strength:** simple, stable and free of parametric assumptions.
- **Limitation:** does not capture the Q3→Q4 recovery or year-end seasonality.
- **Result:** £3.52 M (conservative lower bound).

OLS linear regression (trend + weekly dummies)

Model:

$$volume = \beta_0 + \beta_1 trend + C(day_type) + \varepsilon$$

with HC3 robust standard errors to correct for heteroskedasticity.

We can use this model for the following reasons:

- The daily distribution is non-normal and bimodal → ANOVA is avoided
- OLS with dummies is appropriate because:
    - It isolates the systematic effect of the regimes.
    - It does not require strict normality with HC3.
    - It captures the slight local trend observed in Mon–Thu (rebound Q3→Q4).
- A key finding of this model was the smooth daily trend of ≈ +£11k to £12k/day, consistent with the year-end recovery and typical corporate seasonality.
- **Result:** £5.95M.

Additive Holt–Winters (seasonal period = 7)

Appropriate when stable seasonality and a smooth non-linear trend are present. A 1,500-iteration parametric bootstrap was used to obtain a robust confidence interval given non-normality.

- **Result:** £6.79M
- **95% Bootstrap CI:** £5.34M – £7.91M

On the absence of statistically significant quarterly differences

Non-parametric tests (Kruskal–Wallis and Dunn) show that median Mon–Thu levels in Q2, Q3 and Q4 are not significantly different.

However, this does not imply that the global historical average (£3.47 M) is an appropriate forecasting estimator, because:

- The global average mixes three structurally distinct regimes.
- Liquidity planning is driven solely by Mon–Thu, which operates stably at ≈ £5.2 M and accounts for 82 % of volume.
- Lack of quarterly significance indicates regime stability, not absence of a local trend.
- Both Holt–Winters and OLS capture the Q3→Q4 rebound, which manifests as a soft positive trend consistent with corporate year-end patterns.

The central forecast of ≈ £5.3–5.4 M is therefore fully consistent with the statistical evidence and reflects the operational level of the dominant regime.

Comparative results:

Method	**October estimate (£)**
Stratified mean	£3,524,462
OLS regression (trend + day)	£5,950,109
Holt-Winters	£6,786,712
Holt-Winters 95% CI	£5,335,732 – £7,914,028

Despite their differences, all three methods convey a coherent message:

- The stratified mean acts as a lower bound.
- Models incorporating weekly structure capture the post-summer recovery and true operational dynamics.
- 95 % plausible scenarios are concentrated between £5.33 M and £7.9 M, providing a robust and defensible operating range.
- Risk of a scenario below £4.9 M is extremely low.

The combination covers both model uncertainty (dispersion across methods) and statistical uncertainty (bootstrap interval).

Operational recommendation for Treasury

- **Central estimate (average of the three methods):** £5.4M
- **Reasonable operating range:** £3.52M – £6.79M
- **Stress testing floor:** £4.9M
- **Year-end optimistic scenario:** up to £7.9M

This range incorporates weekly seasonality, structural stability of the Mon–Thu regime and the soft positive year-end trend.

Note 1: £3.52M is a conservative historical estimate calculated using a stratified method. It is not a probability; dynamic methods and bootstrapping (H-W) place the highest probability density above £5.3M, so the empirical probability of observing a total < £4.9M is very low.

Note 2: Although not formally tested in this analysis, residual autocorrelation should be checked in future iterations (e.g. Durbin–Watson or Ljung–Box on the OLS and Holt–Winters residuals). If significant serial correlation is detected, standard errors could be upgraded to HAC (Newey–West) or the forecasting suite could be extended with explicit ARIMA/ETS components as additional robustness checks. In the current exercise, the additive Holt–Winters already serves as a time-series benchmark that implicitly accounts for short-term dynamics, while the HC3-robust OLS provides a transparent parametric reference.
